Summary
This paper presents a detailed numerical study of the retrogressive failure of landslides in sensitive clays. The dynamic modelling of the landslides is carried out using a novel continuum approach, the particle finite element method, complemented with an elastoviscoplastic constitutive model. The multiwedge failure mode in the collapse is captured successfully, and the multiple retrogressive failures that have been widely observed in landslides in sensitive clays are reproduced with the failure mechanism, the kinematics, and the deposition being discussed in detail. Special attention has been paid to the role of the clay sensitivity on each retrogressive failure as well as on the final retrogression distance and the final run-out distance via parametric studies. Moreover, the effects of the viscosity of sensitive clays on the failure are also investigated for different clay sensitivities.

KEYWORDS
landslides, PFEM, retrogressive failure, sensitive clay, strain softening

1 INTRODUCTION

Landslides in sensitive clays have long been recognised as a challenging problem. Investigations show that, if sensitive clay is present, a seemingly stable area might be subject to a major landslide after a small initial failure. Typical examples of these landslides occurred in Canada,\textsuperscript{1} where they proceeded retrogressively up to even kilometres away from the place they were initiated.

To minimise the degree of destruction that these landslides can cause, a better understanding of their behaviour in sensitive clays is of great importance. Many efforts have so far been made in this respect, for instance through theoretical analysis,\textsuperscript{2-5} experimental tests,\textsuperscript{6-10} and empirical statistics.\textsuperscript{11-14} In these studies, special emphasis was typically given to the triggering mechanisms, the evolution processes, and the retrogression run-out distances. Despite these contributions, landslides in sensitive clays are not yet fully understood. Empirical formulations and analytical solutions indeed provide valuable information; they generally involve simplified assumptions, and the information they yield is limited. Laboratory tests play an important role in understanding landslides. Nonetheless, they are in many cases of high cost as well as of long duration for model construction, especially for centrifuge testing. For these reasons, laboratory tests usually focus on only a limited number of variables. As an alternative, computational modelling can be adopted.

Although detailed parametric studies can be performed in virtual experiments, the numerical simulation of landslides in sensitive clays is never a trivial task. The conventional limit equilibrium method and/or the finite element
strength reduction method are the commonly used approaches for slope stability analysis in engineering practice. Neither of them performs well when sensitive clays are involved. Indeed, both these methods may assign a factor of safety above 1 to a slope which actually is unstable because of their assumption of a perfectly plastic soil model. It is known that landslides in sensitive clays develop in a progressive manner because of the strength reduction of soils. If for any reason (eg, earthquakes, erosion, or human activity) the stress state of a point within a slope moves past its peak strength, the strength at that point may reduce significantly with further deformation. The unbalanced stress is, consequently, transferred to its surrounding material whose peak strength may also be exceeded. The unbalanced stresses continue to migrate in such a manner until a critical failure surface is formed in the slope. This particular type of progressive failure process requires a complete deformation analysis with the strain-softening behaviour of the material being accounted for. However, it is worth noting that the inclusion of the strain softening may result in the solution becoming strongly mesh dependent. This stems from the fact that the related boundary value problem is no longer elliptic in statics or hyperbolic in dynamics as indicated by Belytschko and Lasry. To overcome this issue, special regularisation techniques, such as nonlocal theories or the introduction of artificial viscosity, have to be adopted.

The numerical modelling of the postfailure stage of landslides in sensitive clays is even more complex. For example, in multiple retrogressive earthflows, materials from the initial slide flow out of the generated crater at the front of the deposit leading to a new backscarp which may be unstable and collapse as well. Clays involved in this second failure also migrate away resulting in another new backscarp. Such retrogressive collapse continues until a final stable scarp forms. The state of sensitive clays, in particular, those of high sensitivity (eg, quick clays), may evolve from a solid to a viscous liquid in this process. The transition from a solid-like behaviour to a fluid-like behaviour inevitably leads to extreme material deformation and rapidly changing evolutions of free surfaces. Computational modelling of the postfailure stage of landslides in a sensitive clay thus requires not only an appropriate constitutive model to describe both the solid-like and the liquid-like behaviours of the involved material but also a robust numerical technique that is capable of tackling dramatic changes in the geometry. A recent contribution in this regard was made by Wang et al, who used a large deformation finite element method with mesh regeneration to study the sliding of a marine sensitive clay deposit on a rigid surface. Similarly, Dey et al implemented a strain-softening model into the coupled Eulerian-Lagrangian (CEL) approach in ABAQUS, and applied it to investigate the failure development in a deposit with a thin layer of sensitive clays. The formation process of the backscarp was reproduced successfully. Additionally, the formation of a long shear band in the layers of sensitive clay followed by the dislocation of soils above into a number of soil blocks is also captured. Later, an implicit material point formulation was proposed in Wang et al for modelling the retrogressive failure of a sensitive clay slope. Note that, although landslides in sensitive clays develop in a progressive manner, the computational framework developed in these models usually assumed a perfectly plastic soil model. It is known that this approach is capable of simulating progressive failure of geosignature in sensitive clays with a typical example being the collapse of a column of sensitive clay. Moreover, its effectiveness and robustness in simulating landslides in sensitive clays have been illustrated as well in Zhang et al.

Although the landslide simulation was carried out in Zhang et al, it served as a general example to show the capability of the numerical scheme and the constitutive model. In this study, the computational framework proposed in Zhang et al is adopted for a detailed numerical investigation of the retrogressive landslide in sensitive clays with emphasises on the mechanism of the multiple retrogressive failure mode, the kinematics of the sliding mass, and the resulting deposition (eg, the final run-out distance and the retrogression distance). Special attention is devoted to studying the role of the sensitivity of clays on the failure, including its effects on the final retrogression and run-out distance as well as on each new retrogressive collapse, via parametric studies. Last but not least, the focus is also placed on the effect of the viscosity of clays on the progressively retrogressive failure, in particular, its influence on the final retrogression distance and the final run-out distance when the clays are of different sensitive degrees.

The paper is organised as follows. Section 2 presents the problem considered and the corresponding governing equations for dynamic modelling. The material parameters utilised in the numerical simulation are summarised in Section 3,
and the particle finite element method is described briefly in Section 4. Section 5 then provides the simulation results and discussions before conclusions are drawn in Section 6.

2 PROBLEM DESCRIPTION

To investigate landslides in sensitive clays, the problem illustrated in Figure 1 is studied. The deposit involves a slope of height \( H \) and length \( 2H \). The extent of the deposit is chosen to be sufficiently long so that there is no effect from the fixed boundary on the left. For simplicity, the problem is regarded as plane strain.

Suppose the volume of the deposit is represented by \( \Omega \) and the surface is denoted by \( \Gamma \). The partition of the surface is \( \Gamma = \Gamma_u \cup \Gamma_t \), where \( \Gamma_u \) and \( \Gamma_t \) are the kinematic and traction boundaries obeying the constraint \( \Gamma_u \cap \Gamma_t = \emptyset \) with \( \emptyset \) being a null set. The momentum conservation equations, the kinematic equations for the displacement gradients, and the corresponding boundary conditions then read

\[
\nabla^T \sigma + b = \rho \ddot{u} \quad \text{in} \quad \Omega
\]

\[
\varepsilon = \nabla^T u \quad \text{in} \quad \Omega
\]

\[
u = \bar{u} \quad \text{on} \quad \Gamma_u
\]

\[
N^T \sigma = t \quad \text{on} \quad \Gamma_t
\]

where \( \sigma \) and \( \varepsilon \) are the Cauchy stress and the strain, \( b \) is the body force, \( u \) is the displacement, \( \bar{u} \) and \( \bar{t} \) are the prescribed displacements and external tractions, \( N \) consists of components of the outward normal to the boundary \( \Gamma_u \) and \( \nabla^T \) is the transposed gradient operator. The superposed dot in Equation (1) represents differentiation with respect to time.

Interactions between the deposit (a deformable body) and the basal surface (a rigid boundary) are defined by the nonpenetration conditions:

\[
g_N \geq 0, \quad p \geq 0, \quad p g_N = 0, \quad |q| - \mu_F p \leq 0
\]

where friction is also taken into account. In the above, \( g_N \) is the gap between the material and the rigid surface, \( p \) is the contact pressure which is positive corresponding to compression, \( q \) is the tangential stress, and \( \mu_F \) is the friction coefficient between the material and the surface. The above conditions are imposed on all boundary material points of the deposit. After finite element discretisation, they are imposed on the boundary nodes of the mesh. More details of these nonpenetration conditions can be found in Zhang et al.\(^{29}\) Notably, the rigid surface is usually assumed to be rough for considering its interaction with clays\(^{19}\); it is however not uncommon to make an assumption of a friction contact mechanism between the clay and the rigid base when reproducing real-world landslides in clays\(^{30}\). In this study, the contact between the clay and the basal surface is assumed to be frictional following Llano-Serna et al.\(^{30}\)

The behaviour of the sensitive clay is described by an elastoviscoplastic model with strain softening. If the stress state is inside the yield domain, namely the yield function \( F(\sigma, \kappa) < 0 \) where \( \kappa \) is an internal variable for strain softening, the deformation is elastic. The total strain rate \( \dot{\varepsilon} \) is then the elastic strain rate \( \dot{\varepsilon}^e \) calculated via Hooke’s law as

\[
\dot{\varepsilon}^e = \mathbb{C} \dot{\sigma}
\]
where $\mathbb{C}$ is the elastic compliance matrix. Otherwise, an additive decomposition applies to $\dot{\varepsilon}$ according to

$$ \dot{\varepsilon} = \dot{\varepsilon}^e + \dot{\varepsilon}^{vp} $$

(7)

where $\dot{\varepsilon}^{vp}$ is the viscoplastic strain rate. It has been shown in Locat and Demers$^{31}$ that the classical Bingham model captures the rheological behaviour of Canadian sensitive clays well, and is thus adopted in this work. The total stress is

$$ \sigma = \tau + \eta \dot{\varepsilon}^{vp} $$

(8)

where $\eta$ is the viscosity coefficient, $\tau$ is the stress lying on the boundary of $F(\tau, \kappa) = 0$, and the quantity $\sigma - \tau$ is called the overstress. The viscoplastic strain rate is taken to be normal to the yield surface at $\tau$:

$$ \dot{\varepsilon}^{vp} = \dot{\lambda} \nabla_\tau F(\tau, \kappa) $$

(9)

where $\dot{\lambda}$ is the non-negative plastic multiplier rate and $\nabla_\tau(*)$ denotes the derivative of $(*)$ with respect to $\tau$. In the limiting case of $\eta = 0$, the elastoviscoplastic model reduces to the classical rate-independent elastoplastic model.

The Tresca yield criterion used here may be expressed as

$$ F(\sigma, \kappa) = \sqrt{(\sigma_{xx} - \sigma_{yy})^2 + 4\sigma_{xy}^2 - 2c_u(\kappa)} $$

(10)

where the cohesion softening is also included to capture the basic postfailure behaviour. Following Troncone$^{16}$ and Potts et al.$^{32}$ the strain softening is accounted for by reducing the cohesion $c_u$ using a bilinear function (see Figure 2) of the equivalent deviatoric plastic strain, $\kappa = \int \dot{\kappa} \mathrm{d}t$, where $\dot{\kappa} = \sqrt{0.5(\dot{\varepsilon}^{vp})_{ij}(\dot{\varepsilon}^{vp})_{ij}}$ and $\dot{\varepsilon}^{vp}_{ij}$ is the rate of the deviatoric viscoplastic strain tensor given by

$$ (\dot{\varepsilon}^{vp})_{ij} = (\dot{\varepsilon}^{e})_{ij} - \frac{1}{3} (\dot{\varepsilon}^{e})_{kk} \delta_{ij} $$

(11)

in which $\delta_{ij}$ is the Kronecker delta.

Note that the total stress, rather than the effective stress, is utilised implying undrained conditions. In the field, sensitive clays are of very low permeability and landslides usually occur suddenly with a relevant fast movement of the involved soil mass. In these circumstances, the pore water migrates relatively slowly and thus the undrained approximation is reasonable.$^{18,19,21,25}$

### 3 Selection of Material Parameters

Sensitive clays are commonly classified based on their sensitivity, $S_t$, which is defined as the ratio of their peak strength, $c_{up}$, to their remoulded strength, $c_{ur}$ (see also Figure 2). Most natural clays are sensitive except for heavily overconsolidated and boulder clays. Table 1 illustrates the classification of sensitive clays defined according to Skempton and Northey.$^{33}$ Clays with $1 < S_t \leq 2$ are regarded as having low sensitivity. Normally consolidated clays are usually of medium sensitivity $2 < S_t \leq 4$, while highly sensitive clays of $4 < S_t \leq 8$ are also encountered frequently in the field. Clays are considered to be extra-sensitive if $S_t > 8$ and to be quick if $S_t > 16$. To select appropriate material properties, the correlation between the remoulded undrained strength and the sensitivity of clays involved in real-world landslides that occurred in Canada$^{11}$ and Norway$^2$ are drawn in Figure 3 where the properties of sensitive clays in some

![Figure 2](https://www.scipedia.com)
offshore sites\textsuperscript{34,35} are also included. Because the geometry of the deposit is fixed in this study, the intact undrained shear strength is set to be 22 kPa (corresponding to the solid line in Figure 3) so that the factor of safety of the initial slope is fixed in all cases. The sensitivity, however, varies in parametric studies carried out in Section 5.2 to cover the range of \( \text{St} \) given in Table 1. Notably, the undrained shear strength in practice usually increases with the depth; the value of 22 kPa used in this study is assumed to be the average undrained shear strength of the deposit, which is a common approximation when modelling a landslide in clays.\textsuperscript{19,20}

According to Quinn et al,\textsuperscript{5} the relation between the shear stiffness, \( G \), and the peak shear strength, \( c_{\text{up}} \), for undisturbed sensitive clays yields \( G/c_{\text{up}} \approx 30 \sim 100 \). Given that \( c_{\text{up}} \) is assumed to be 22 kPa and Poisson ratio is set to be

\begin{table}[h]

Young modulus \( E \) & \( 4.26 \times 10^6 \) Pa \\
Poisson ratio \( \nu \) & 0.49 \\
Unit weight \( w \) & 20 kN/m\textsuperscript{3} \\
Reference equivalent deviatoric plastic strain \( \mathcal{R} \) & 0.6 \\
Peak cohesion \( c_{\text{up}} \) & 22 kPa \\
Sensitivity \( \text{St} \) & 6 \\
Viscosity coefficient \( \eta \) & 500 Pa s \\
Friction coefficient \( \mu_F \) & 0.36 \\
\hline
\end{tabular}
\end{table}
0.49 to approximate undrained (constant volume) conditions, after determining \( G \), Young modulus \((E)\) can be calculated which ranges from \( 1.96 \times 10^6 \text{Pa} \) to \( 6.55 \times 10^6 \text{Pa} \). In all simulations, an average value of \( E = 4.26 \times 10^6 \text{Pa} \) is adopted. The unit weight is assumed to be \( w = 20 \text{kN/m}^3 \), which is typical for a sensitive clay,\(^7\) and the reference equivalent deviatoric plastic strain is \( \kappa = 0.6\) according to Quinn et al.\(^5\) Back calculations of various subaerial and submarine slides in Edgers and Karlsrud\(^23\) and Johnson and Rodine\(^24\) suggested the value of viscosity ranging from 100 to 1499 Pa s, which is in line with the value used for reproducing the Storegga slide in a sensitive marine clay in Gauer et al.\(^25\) Thus, the viscosity of the clays in the reference analysis is assumed to be 500 Pa s which is within the suggested range. Its influence will also be investigated via parametric studies. The basal surface is assumed to have a friction coefficient of 0.36. For the sake of convenience, the reference material parameters utilised in the simulation are listed in Table 2.

4 PARTICLE FINITE ELEMENT MODELLING

The particle finite element method (PFEM)\(^28,36,37\) is adopted for the numerical simulation in this study. The PFEM is a mixture of the Lagrangian finite element method (FEM) and the particle approach. The simulation in a typical time interval \([t_n, t_{n+1}]\) proceeds by first solving the governing equations on the meshes \((M_n)\) as shown in Figure 4) assigned to the computational domain using the Lagrangian FEM. After the mesh nodes are updated to their new positions according to the computed displacement increment, they are considered as free particles denoted by \( C_{n+1} \) in Figure 4. The new computational domain \( \Omega_{n+1} \) is identified on the basis of \( C_{n+1} \), using the so-called alpha-shape method, and then discretised using a new mesh. After mapping the state variables (such as velocities, accelerations, stresses, and strains) to the new mesh \( M_{n+1} \), an incremental finite element analysis is conducted again and the simulation then steps into the next time interval.\(^28\) Because of its nature, the PFEM inherits not only the ability of a particle approach to handle general large deformation problems but the solid mathematical foundation of the conventional finite element method. To date, the PFEM has been used to tackle problems such as granular flows,\(^38-41\) the modelling of a real-world flow-like landslide,\(^29\) and the simulation of landslide-generated waves.\(^42,43\) Here, the version of the PFEM presented in Zhang et al.\(^26\) is applied where a mixed variational principle is used to cast the governing equations for elastoviscoplastic analysis as an equivalent optimisation problem, which is then solved using an interior-point optimisation algorithm. A major advantage of this scheme is the convergence behaviour of the solution, regardless of

![FIGURE 4](https://www.scipedia.com)
whether or not the previously solved known states are close to the new unknown states. Such a feature is of great importance in the simulation of landslides, because dramatic changes in the stress or the deformation may occur in a single time interval. More details of the solution algorithm can be found in Zhang et al., where the reformulation, the implementation, and the verification have been documented.

5 RESULTS AND DISCUSSIONS

5.1 Analysis using reference parameters

The problem is first studied using the reference parameters listed in Table 2. Failure of the deposit is triggered by removing the head load, representing an erosion of the slope toe or excavation (Figure 1). The length of the deposit, 100 m, is sufficiently long to remove the boundary effect. A mixed quadratic displacement/linear stress isotropic triangular element is adopted, and the mesh size is 0.6 m (0.066H) leading to a total of 8445 triangular elements and 17248 mesh nodes for the discretisation of the initial computational domain. The simulation proceeds until the final deposit is computed using a time step $\Delta t = 0.025$ second.

5.1.1 Failure mechanism

The complete failure process of the deposit because of the retreat of the head load is illustrated in Figure 5. As shown, the slope is unstable after the head load is removed. The shear stress at the bottom layer of the slope increases considerably which leads to the yielding of the clay there (Figure 5A). An apparent shear band denoted by $C1S1$ (eg, the first shear band in the first retrogressive collapse process) emerges, and the plastic strain accumulates at the bottom of the initial slope (Figure 5A). Later, a second shear band, $C1S2$ (the second shear band in the first retrogressive collapse process), emerges as shown in Figure 5B. $C1S2$ propagates from the bottom to the top surface of the deposit making the disturbed material migrate in a rotational manner which is a typical pattern in slope failure. Rather than rotating as a rigid body, the disturbed clay disintegrates into 2 pieces owing to the emergence of the third shear band $C1S3$.

FIGURE 5 Retrogressive failure of the deposit. Colours are proportional to the accumulated equivalent deviatoric plastic strain. Symbol $CiSj$ denotes the $j$th shear band in the $i$th retrogressive collapse, and $Mi$ denotes the clay disturbed in the $i$th retrogressive collapse.

[Colour figure can be viewed at wileyonlinelibrary.com]
(Figure 5C) and then further into 3 pieces because of the fourth shear band C1S4 (Figure 5D). Both the shear bands C1S3 and C1S4 originate from the bottom layer of the slope and propagate towards the inclined front surface. Such a failure mechanism of a slope in sensitive clay is termed the multiwedge failure model.44

The migration of the clays evoked in the first retrogressive collapse (e.g., the mass in the range of M1 as shown in Figure 5D) results in the generation of a new backscarp. This new backscarp is unstable as well (Figure 5E) and fails following the same collapse pattern—the multiwedge failure mode. Four major shear bands (namely C2S1, C2S2, C2S3, and C2S4 as shown in Figure 5E, F) emerge sequentially in this retrogressive collapse process and clays involved in this second collapse migrate forwards. Such progressively retrogressive failure continues (Figure 5G) until a stable backscarp is formed (Figure 5H). For the studied problem, the retrogressive failure occurs 4 times (Figure 5H) leading to a considerable amount of materials stored in front of the final stable backscarp. The final run-out distance of the concerned landslide is 40.5 m, and the final retrogression distance is 37 m.

5.1.2 Kinematics

Figure 6 shows the variation of the velocity of the sliding front and the maximum velocity of the sliding clay mass in the collapse process. The horizontal velocity of the sliding front increases the moment the head load is removed owing to the transformation of the gravitational potential energy of the disturbed clay into its kinetic energy. After reaching a peak value, the front velocity decreases steadily to zero because of the plastic dissipation and the basal friction. At this reduction stage, the sliding front does not always possess the maximum horizontal velocity. As shown in Figure 6, the horizontal velocity of the sliding front is much lower than the maximum horizontal velocity at \( t = 10.4 \) seconds and \( t = 14.9 \) seconds. On the other hand, the vertical velocity of the sliding front is always zero throughout the failure process, whereas the maximum vertical velocity fluctuates with 4 local maximum values at time instants of 2.9, 6.65, 10.4, and 14.9 seconds, respectively.

To better understand the kinematics, contours of the horizontal and vertical velocities at these 4 time instants, when local maximum values of vertical velocities are obtained, are illustrated in Figure 7. Additionally, curves of the horizontal velocity (\( V_x \)) and the vertical velocity (\( V_y \)) along the plane \( y = 2 \) m (white dashed lines) are drawn. For each retrogressive collapse, the disturbed clay slides in a rotational manner and can be decomposed approximately into 2 wedges according to their kinematic characteristics (Figure 7B). The upper wedge has the maximum vertical velocity, with a negative sign indicating downward movement caused by the release of the gravitational potential energy, while the lower wedge moves upwards with a very small velocity because of squeezing. The mass that is not involved in the current collapse moves with a relatively low vertical speed. Thus, the maximum velocity fluctuates whenever a new retrogressive failure is triggered. In contrast, the horizontal velocities of both the upper and lower wedges are positive, indicating that they are moving forward (see Figure 7A). The lower wedge, however, moves much faster than the upper wedge. Unlike the vertical velocity, the horizontal velocity of the sliding front is always considerable in the collapse process. The maximum horizontal velocity during the first 2 collapses (Figure 7(a1) and (a2)) occurs at the sliding front. Although it decreases because of the plastic dissipation and the basal friction, the horizontal velocity of the sliding front

![FIGURE 6 Variations of the horizontal and vertical velocities of the sliding front and the maximum horizontal and vertical velocities](https://www.sciencedirect.com)
5.1.3 Mesh dependence

The inclusion of the strain-softening behaviour in a rate-independent constitutive model raises the possibility of mesh dependence in that the width of a shear band is governed by the mesh size. Fortunately, the elastoviscoplastic model adopted here implicitly introduces a length scale to the corresponding boundary-value problem and thus circumvents this issue. As stated in Moore and Rowe, however, it is computationally inefficient to capture the small thickness of potential shear bands with a purely continuum model when large-scale practical problems are considered. In this study, we aim to obtain converged solutions regarding the failure patterns and the kinematics of the progressively retrogressive failure rather than to capture the exact width of the shear band which is very thin.

Figure 8 shows the curves of the retrogression distance and the run-out distance against time for the problem modelled using coarse, medium, and fine meshes. The element sizes (the length of the element edge) for these cases are 0.8, 0.6, and 0.4 m, respectively, leading to the total numbers of elements used for discretising the initial domain being 4800 (9875 mesh nodes), 8445 (17248 mesh nodes), and 19116 (38773 mesh nodes). As depicted in Figure 8, converged solutions for both the retrogression distance and the run-out distance are obtained when using the medium and fine meshes. Furthermore, the final depositions obtained from the simulations are compared in Figure 9 where a satisfactory agreement is also achieved. In the following, all simulations were conducted using meshes of a medium size unless otherwise specified.

5.2 Effect of sensitivity

To investigate the influence of the clay sensitivity on the retrogressive failure of the deposit, the problem is simulated using St ranging from 1 (for insensitive clay) to above 16 (for quick clay) with the rest of the parameters being the same as listed in Table 2.

As shown in Figure 10, the profile of the final deposition is very dependent on the sensitivity St. For the deposit in non-sensitive clays (Figure 10A), the slope fails because of the retreat of the head load and a clear shear band is
FIGURE 8 Variations of (A) the retrogression distance and (B) the run‐out distance against time from simulations using meshes of different sizes [Colour figure can be viewed at wileyonlinelibrary.com]

FIGURE 9 Final depositions of the retrogressive failure from simulations using different meshes [Colour figure can be viewed at wileyonlinelibrary.com]
FIGURE 10  Final depositions of the retrogressive collapse for the deposit in sensitive clays with sensitivity (A) $St = 1$, (B) $St = 2$, (C) $St = 4$, (D) $St = 8$, and (E) $St = 12$. Colours are proportional to the accumulated equivalent deviatoric plastic strain. $C_i$ refers to the $i$th retrogressive collapse [Colour figure can be viewed at wileyonlinelibrary.com]

FIGURE 11  Variation of (A) the retrogression distance and (B) the run-out distance of the deposit failure in sensitive clays of different $St$. [Colour figure can be viewed at wileyonlinelibrary.com]
observed. Nevertheless, after undergoing very limited deformation the slope becomes stable again. This is because the factor of safety of the slope, estimated using the peak cohesion, is close to 1 and the material has no reduction in strength as the slope deforms. For the deposit in a clay of low sensitivity \((S_t = 2)\), the initial slope also fails and the disturbed clay moves away from the newly generated backscarp (Figure 10B). This new backscarp deforms slightly before becoming stable again. A further increase in the sensitivity of the clay leads to more times of the retrogressive failure as shown in Figure 10C to E. A total of 3, 5, and 6 retrogressive failures are observed for the deposit in a medium \((S_t = 4)\), highly sensitive \((S_t = 8)\), and extra-sensitive \((S_t = 12)\) clay as illustrated in Figure 11A where the retrogression distance is plotted against time. This phenomenon can be explained by the fact that same plastic deformation leads to a much lower strength for clays of higher sensitivity. The newly generated backscarp in clays of higher sensitivity is thus more prone to retrogressive failure, and, consequently, a larger retrogression distance will be obtained (Figure 11A). Although the sensitivity influences the times of the retrogressive failure, the increment of the retrogression distance induced by each failure seems to be independent of the sensitivity of clays (Figure 11A). Regarding the run-out distance, Figure 11B indicates that higher sensitivity leads to a larger final run-out distance. Furthermore, it can also be concluded from Figure 11B that the speed of the sliding front (which is the gradient of the curve) is also much larger when the sensitivity is high. Indeed, less energy is dissipated when the clay is fully remoulded because the residual shear strength for higher sensitive clays is much lower. Consequently, a larger proportion of the gravitational potential energy of clays is transformed into their kinematic energy during the collapse that results in a higher speed.

It is also notable that intact clays with a higher sensitivity are more prone to erosion in the sliding process (Figure 10). For the low-sensitive case \((S_t = 2)\), the block of clays involved in the first retrogressive collapse is divided into 3 undisturbed pieces with remoulded clays existing in between as illustrated in Figure 10B, whereas, for the medium-sensitive case \((S_t = 4)\), the undisturbed pieces resulting from the first collapse are smaller (Figure 10C). For the highly sensitive and the extra-sensitive cases (e.g., \(S_t = 8\) and 12), most of the clays involved in the first collapse have been fully remoulded in the sliding process (Figure 10D, E). Moreover, the surface of the final deposition for \(S_t = 12\) is much smoother than those for \(S_t = 2\) and 4. This is owing to the much lower residual shear strength of the extra-sensitive clay that it exhibits semifluid behaviour after being fully remoulded.

To further reveal the effect of the strength reduction on the final deposition, plots of the normalised retrogression distance (i.e., the ratio of the retrogression distance to the height of the deposit \(H\)) and the normalised run-out distance (i.e., the ratio of the run-out distance to the height of the deposit \(H\)) as functions of the sensitivity \(S_t\) are shown in Figure 12. As expected, increasing sensitivity leads to an increase of both the retrogression distance and the run-out distance. Owing to the fact that the sensitivity \(S_t\) is a power function rather than a linear function of the remoulded strength, the change rate declines somewhat as \(S_t\) increases. Alternatively, the brittleness of the clay, \((c_{up} - c_{ur})/c_{up}\), which is a linear function of the remoulded strength and ranges from 0 to 1, can be used to characterise the normalised retrogression and run-out distances.\(^{46}\) As shown in Figure 13, both the retrogression distance and the run-out distance increase sharply when the brittleness of the clay approaches 1. In other words, when the remoulded strength is infinitesimal, both the run-out distance and retrogression distance become unbounded.

5.3 Effect of viscosity

The effect of viscosity on the retrogressive collapse in a sensitive clay is studied by using different viscosity values ranging from 1 to 1000 Pa s. This range covers the range of viscosity from both the laboratory tests of a small sample and the back calculation of real-world landslides in sensitive clays. The sensitivity of clays in this case is St = 4 with other material parameters being the same as those listed in Table 2.

Plots of the retrogression distance and the run-out distance against time, for various viscosities, are shown in Figure 14. It is clear that an increase in the viscosity leads to a decrease in the final run-out distance (Figure 14A). The final run-out distance for \( \eta = 10 \) Pa s is 35.72 m, whereas it is 31.65 m for \( \eta = 100 \) Pa s and 23.35 m for \( \eta = 1000 \) Pa s. This follows from the fact that more energy is dissipated because of viscoplastic deformation when a higher value of viscosity is adopted. In contrast, the relation between the duration of the sliding and the viscosity is not clear from Figure 14A. Indeed, although lower viscosity results in a larger final run-out distance, the leading front also moves at a relatively higher speed. The final retrogression distance is also influenced by the viscosity of the clay. As shown in Figure 14B, 4 times of retrogressive collapse occur for \( \eta = 10 \) and 100 Pa s resulting in a retrogression distance of 35.85 m, whereas the deposit collapses 3 times for \( \eta = 1000 \) Pa s. Figure 14B also shows that the incremental retrogression distance induced in each collapse is the same regardless of the viscosity. Indeed, the retrogression distance increases when the shear band propagating from the bottom to the top surface (e.g., C1S2 and C2S2 in Figure 5) emerges. During this period, the material located in the shear band moves at a very slow speed and the influence of the viscosity is small.

Figure 15 illustrates the final depositions obtained from the simulations using \( \eta = 10, 100, \) and 1000 Pa s. It shows that the failure mode of the retrogressive collapse is independent of the viscosity. Nonetheless, clays are prone to erosion when the viscosity is low. As shown, clays involved in each collapse for \( \eta = 10 \) Pa s disintegrate into much smaller pieces, and more remoulded clays are observed at the front of the deposit when the viscosity is low.

Studies on the influence of the viscosity when the sensitivity of the clay differs are also carried out. Figure 16 shows the final run-out distance and the retrogression distance for St = 1, 2, 4, and 8, respectively. Because the factor of safety for the initial slope is close to 1, the slope in nonsensitive clay (St = 1) turns out to be stable again after undergoing very limited deformation. In this case, the clay exhibits solid-like behaviour, and thus, neither the run-out distance nor the retrogression distance is impacted by the viscosity (Figure 16A). In the case of St = 2 (low-sensitive clays), the effect of the viscosity on the retrogression distance is still negligible, but the final run-out distance increases from 7.35 m for high viscosity \( \eta = 1000 \) Pa s up to 11.4 m for low viscosity \( \eta = 1 \) Pa second (Figure 16B). Not surprisingly, the influence of the viscosity on the retrogression and run-out distances is considerably large for medium and highly sensitive clays. For the medium-sensitive case (St = 4), Figure 16C indicates a 38.46% (from 26.55 to 36.02 m) and a 52.42% (from 23.35 to 35.58 m) increase in the retrogression distance and the run-out distance, respectively, when the viscosity decreases from 1000 to 1 Pa s. For the high-sensitive case (St = 8), the retrogression distance and the run-out distance experience an 82.78% (from 35.78 to 65.4 m) and a 73.48% (from 43.81 to 76.0 m) increase, respectively, when the viscosity decreases from 1000 to 1 Pa s according to Figure 16D. This phenomenon again reflects that remoulded clays behave more like a liquid when the sensitivity is high. It is also notable that, when the viscosity \( \eta \) is less than 10 Pa s, further decrease of viscosity will not result in apparent difference in the final run-out distance and the retrogression distance.

6 CONCLUSIONS

In this paper, the retrogressive failure of a deposit in sensitive clay is studied numerically using the PFEM with a strain-softening elastoviscoplastic model proposed in Zhang et al.\textsuperscript{26} The complete process of multiple retrogressive failures is reproduced successfully.

The multiwedge failure mode composed of 4 main plastic shear bands is reproduced in this study. The complete progressively retrogressive failure of the slope consists of a series of multiwedge failures of new backscars. In detail, the clay involved in each collapse disintegrates into intact blocks that move like rigid bodies, with the material in the shear bands being fully remoulded and behaving like a fluid. Under continuing deformation, these blocks may decompose further into small pieces during the sliding process. The removal of the clay from the front of a newly generated backsnap may result in further retrogressive collapse. A sequential series of such failures occur until a stable backsnap forms. In spite of the mass in front of the newly generated backsnap, the increment of the retrogression distance induced in each new failure is nearly the same. The speed of the sliding front is always considerable compared to the rest of the slope material throughout the process.

Parametric studies on the influence of the sensitivity and the viscosity of clay have also been conducted. The sensitivity impacts the form of the retrogressive failure significantly. Clays of higher sensitivity are more prone to erosion during the sliding process. An increased sensitivity results in an increase in both the final run-out distance and the retrogression distance. When the remould shear strength \( c_{ur} \rightarrow 0 \), both the final run-out distance and the retrogression distance become very large, indicating that unexpected large retrogressive landslides are more likely to occur in sensitive clays of low remoulded strength. For landslides in clays of higher sensitivity, it also takes a longer time for the sliding front to stop completely.

The viscosity of the clay affects the failure. Decreasing the viscosity results in more times of retrogressive failures, and thus increases the corresponding run-out and retrogression distances. Moreover, the intact block of clays resulting from the multiwedge failure is more likely to break up into small fragments when the viscosity is low. However, the viscosity plays a different role in the final run-out distance and the retrogression distance when the clay sensitivity varies. For higher sensitive clays (normally low remoulded shear strength), the influence of the viscosity is more apparent (for instance resulting in a large change in the final run-out distance and the retrogression distance), because, in this case, the remoulded clay behaves more like a liquid. On the other hand, when the sensitivity is low, the clay behaves like a solid even after being fully remoulded in which case the viscosity has a very limited influence.
Although both the sensitivity and the viscosity of clays considerably impact the number of retrogressive failures, neither of them has considerable influence on the increment of the retrogression distance induced in each new failure.
