Abstract

A closed form for the computation of the dipolar and monopolar influence coefficients related to a low-order panel method is shown. The flow problem is formulated by means of a three-dimensional potential model; the method of discretization is based on the Morino formulation for the perturbation velocity potential. On the body surface this representation reduces to an integral equation with the source (or monopolar) and the doublet (or dipolar) densities. The former is found by application of the boundary condition, and the latter is the unknown over the surface of the body. The lower panel method is used for the analytical integrations of the monopolar and dipolar influence coefficients, with special attention to avoid a logarithmic singularity in the monopolar matrix when flat fairly structured meshes that are common in ship-wave calculations are used. © 2000 Elsevier Science Ltd. Keywords: Potential flows; Closed forms; Low-order panel methods; Singularity subtraction

1. Introduction

Panel methods are well known and widely accepted in aerospace [1,2] and in naval industry [3,4] for calculating potential flows. In some problems a two-dimensional approach is sufficient, for instance, flows past multicomponent airfoils, infinite cascade, ground effects and wind tunnels [5,6] whereas in other cases a three-dimensional approach is necessary. There exist many types of panel methods for the last case. For exterior potential flows without a free surface, three types of singularity, or surface density, can be used in the numerical solution: only-sources (monopoles), only-dipoles (dipoles) or mixed distributions. For non-lifting flows only-sources may be used, while a lift requires the third type. All these take about the same computational effort. However, as Hunt [2] states, the choice of mixed distributions leads to better results than only-source or only-dipole distributions, as it reduces leakage considerably. Most panel codes originate from the very well known Hess and Smith [7] method, see Refs. [1,2,8]. In practice, the body surface is approximated by quadrilateral or triangular panels. The zero-order methods use plane panels with a constant surface density, while in higher order methods the panels may be curved and the surface density varied in some prescribed manner [9]. The most widely used technique for ship-like problems, is the so-called Rankine source method, which is extensively reviewed in Refs. [3,10,11]. Most Rankine source methods originate from the Hess and Smith method where both the body surface and the free surface are discretized. A successful way of incorporating the free surface boundary condition, which was obtained from a so-called double model solution, was proposed by Dawson [12]. The kinematic boundary condition on the body surface specifies zero normal velocity, which is equivalent to setting the normal derivative of the velocity potential to zero, i.e. a Neumann boundary condition. An alternative formulation for a closed body is to set the potential equal to a constant inside the body surface, i.e. a Dirichlet boundary condition. An overview of the latter approach is shown in Ref. [1]. For the linear, three-dimensional, zero-speed problem of a vessel in sinusoidal waves using panel methods see Refs. [13–17]. For the solution in the time domain and the propeller problem in unsteady flow see Refs. [18–23]. The Morino [24,25] approach is a mixed formulation that involves the computation of surface integrals with both monopolar and dipolar kernels. These surface integrals can be obtained with the aim of closed or numerical integration formulas. Closed formulas are only available for low-order panel formulations and can be obtained with several approaches [7,26,27]. In the Medina and Ligget [27] approach, the surface integral over each flat panel is replaced by its closed contour integration, and a local side term is used for each side contribution, so it can be seen as a rotational tern strategy. When this strategy is
employed for panels with constant dipolar and monopolar surface layers, or panels of zero order, a singularity appears in rather special situations, for instance, in flat structured meshes that often appear in ship-wave calculations. In previous works we have considered alternative methods for potential flows with a free surface, as the ship-wave resistance problem [27–31]. In this case, we need to compute the basic flow over a reference plane, such as the hydrostatic equilibrium plane, with a fairly structured panel mesh due to some properties of the Dawson approach, but in such cases the monopolar integral can be ill-conditioned or undefined since a logarithmic singularity occurs. In this work we show in detail the rotational methodology for zero-order panels, where the logarithmic singularity is eliminated by means of a singularity subtraction.

2. Potential formulation review

Fig. 1. Local side term \( p \eta \) on the \( L^2 \) side.

We consider for brevity a constant speed. The fluid occupies the unbounded region \( \Omega \) exterior to the wetted surface of the body \( \Gamma_s \). The \( x \)-axis is parallel to the upstream non-perturbed velocity \( \mathbf{u}_s \), the \( z \)-axis positive upwards. The potential velocity field \( \mathbf{u} \) is given by \( \mathbf{u} = \mathbf{V} \Phi \), where \( \Phi \) is the total potential, which satisfies the Laplace equation in the flow region \( \Omega \) and can be split as \( \Phi = \mathbf{u}_s^T \mathbf{x} + \phi \) where \( \mathbf{x} = (x, y, z) \) is the position vector and \( \phi \) is the perturbation potential. The kinematic boundary condition is the slip condition \( \partial_n \Phi = 0 \) at the wetted body surface whereas at infinity the perturbation velocity tends to zero for external flows, i.e. \( \phi(x) \rightarrow 0 \) for \( |x| \rightarrow \infty \). Then, the governing equations for the solution \( \Phi \) of the potential flow model are:

\[
\Delta \Phi = 0 \text{ in } \Omega; \quad \partial_n \Phi = 0 \text{ at } \Gamma_s; \\
\Phi \rightarrow \mathbf{u}_\infty^T \mathbf{x} \text{ for } |x| \rightarrow \infty. 
\]

3. Panel formulation

The panel mesh considered here employs a low-order representation of the body surface by means of a polyhedral with \( n \) flat surfaces over the wetted body surface. We employ a low-order panel formulation, with collocation at the centroids of the panels, to set up a discrete linearized system of algebraic equations, where the system matrix is square of dimension \( N = n \). The equation system of the panel method for the flow problem can be written as, \( \mathbf{H} \mathbf{u} = \mathbf{b} \), where \( \mathbf{H} \) is the matrix system, \( \mathbf{u} = -\mathbf{\phi} \) is the basic bipolar vector evaluated at the centroids of the \( N \)-panels, equal to minus the basic potential vector \( \phi = \left[ \ldots \phi(x_i) \ldots \right]^T \) and \( \mathbf{b} \) the source vector. The matrix system is the sum \( \mathbf{H} = 1/2I + \mathbf{A} \), of the scaled identity matrix \( I \) and the bipolar influence matrix \( \mathbf{A} \). The source vector \( \mathbf{b} = \mathbf{C} \mathbf{r} \), is the product of the monopolar influence matrix \( \mathbf{C} \) and the flow vector \( \mathbf{r} = \left[ \ldots \sigma(x_i) \ldots \right]^T \), obtained by means of the slip condition on the solid walls where the normal velocity component is null \( \sigma(x_i) = -\mathbf{u}_s^T \mathbf{n}(x_i) \) for \( j = 1, 2, \ldots, N \), where \( \mathbf{n}(x_i) \) is the \( j \)-unit panel oriented normal to the wetted side, so it can be seen as a kinematic source vector. The bipolar and monopolar influence coefficients \( A_{ij}, C_{ij} \) are given by the surface integrals

\[
A_{ij} = \frac{1}{4\pi} \int_{r_i} d\Gamma \frac{r_i^T \mathbf{n}}{|r_i|^3} \quad \text{and} \quad C_{ij} = \frac{1}{4\pi} \int_{r_i} d\Gamma \frac{1}{|r_i|^3}
\]

\[
\text{for } i,j = 1, 2, \ldots, n; 
\]

where \( r_i \) is the panel unit normal oriented to the wetted side, \( r_i = |x_i - x_j| \) is the distance between the centroid \( x \) and the integration point \( x_j \) over the \( j \)-panel surface, with \( x = (x, y, z) \), where both influence matrices \( \mathbf{A} \) and \( \mathbf{C} \) are dense and non-symmetric in general.

For the monopolar matrix \( \mathbf{C} \), we suppose a flat panel of \( M \) sides and we consider the integral

\[
\tilde{C}_{ij} = \int_{S_j} \frac{1}{r} dS 
\]

\[
\text{where } \tilde{C}_{ij} = C_{ij}/4\pi, S_j \text{ is the } j \text{-panel surface and } r \text{ the length between the collocation point } x \text{ and the integration point } y \text{ over the panel surface, see Fig. 1. We employ the Medina and Ligget strategy [27], where we find an auxiliary function } V(R, \eta) \text{ such that its bidimensional Laplacian } \Delta_{pq} V \text{ over the panel surface is equal to the monopolar kernel } 1/r, \text{ i.e.}
\]

\[
\Delta_{pq} V = \frac{1}{r};
\]

with \( r = \sqrt{R^2 + \eta^2} \), where \( R = \sqrt{p^2 + q^2} \) is the projection of the position vector \( r \) over the panel plane and \( \eta \) the length between the collocation point \( x \) and the plane (constant). Then, we convert the surface integral into a line integral by means of the 2D-divergence theorem

\[
\tilde{C}_{ij} = \int_{S_j} \Delta_{pq} V \, dS_{pq} = \int_{L_j} (\nabla_{pq} V, s) \, dL;
\]
where $s$ is the planar normal unit to the sides $L_i$, $\Delta_{pq}$ is the planar Laplacian operator in the $p, q$-coordinates and $V(R, \eta)$ a regular function. The auxiliary monopolar function $V(R, \eta)$ is found solving the differential equation

$$\frac{1}{R} \frac{\partial}{\partial R} \left( R \frac{\partial V}{\partial R} \right) = \frac{1}{\sqrt{R^2 + \eta^2}},$$

(6)

where $\Delta_{pq} V$ is the bidimensional Laplacian in the $R, \theta$ polar coordinates, with $\partial_p V = 0$. The integration process gives

$$V(R, \eta) = \sqrt{R^2 + \eta^2} + |\eta| \ln \left( \frac{R}{\sqrt{R^2 + \eta^2} + |\eta|} \right),$$

(7)

which admits the solution [32]:

$$V(R, \eta) = \sqrt{R^2 + \eta^2} + |\eta| \ln \left( \frac{R}{\sqrt{R^2 + \eta^2} + |\eta|} \right).$$

(8)

for $R > 0$.

The monopolar integral along the $L^k$ side is written as:

$$\tilde{C}^k = F(p_{k+1/2}, q, \eta) - F(p_{k-1/2}, q, \eta);$$

(12)

where $p_{k+1/2}, p_{k-1/2}$ are the extreme abscissas of the $L^k$ side and $q$ is the common ordinate, which are obtained as $p_{k+1/2} = (x_{k+1/2} - x_k) \mathbf{t}_k$ and $q = (x_{k+1/2} - x_k) \mathbf{s}_k$, where $\mathbf{t}_k, \mathbf{s}_k$ are the tangential and normal planar unit vectors of the $L^k$ side on the panel surface. The sequence sense is such that $\mathbf{s}_k \times \mathbf{t}_k = \mathbf{n}_k$, where $\mathbf{n}_k$ is normal unit vector to the panel.

The auxiliary function $F = F(p, q, \eta)$ is the sum:

$$F = -q F_1 + |\eta| q F_2 + |\eta| q F_3;$$

(13)

where the first integral is

$$F_1 = \int_{p_{k+1/2}}^{p_{k+1/2}} \frac{dp}{\sqrt{p^2 + (q^2 + \eta^2)}} = \ln[p + \sqrt{p^2 + (q^2 + \eta^2)}];$$

(14)

and the second one is

$$F_2 = \int_{q_{k+1/2}}^{q_{k+1/2}} \frac{dp}{p^2 + \eta^2} = \frac{1}{q} \tan^{-1} \frac{q}{\eta};$$

(15)

For the third integral we introduce the variable change $p = \sqrt{q^2 + \eta^2} \sinh \xi$, then:

$$F_3 = \int_{\xi_{k+1/2}}^{\xi_{k+1/2}} \frac{d\xi}{\sqrt{q^2 + \eta^2} \cosh \xi - |\eta|};$$

(17)

with the solution [29]

$$F_3 = \frac{2}{q} \tan^{-1} \left( \frac{\sqrt{q^2 + \eta^2} e^{\xi} - |\eta|}{q} \right).$$

(18)

Now, we express $\xi(p)$ with

$$\sinh(\xi) = \frac{p}{\sqrt{q^2 + \eta^2}} = z;$$

(19)

then $v^2 - 2zv - 1 = 0$, where $v = e^\xi$, and its solution is $v = z \pm \sqrt{z^2 + 1}$. From this we obtain

$$e^\xi \sqrt{q^2 + \eta^2} = p \pm \sqrt{p^2 + q^2 + \eta^2}. $$

(20)

It can be shown that the negative sign is the correct choice; then $F_3$ is written as

$$F_3 = \frac{2}{q} \tan^{-1} \left( \frac{p - |\eta| - \sqrt{p^2 + q^2 + \eta^2}}{q} \right);$$

(21)

where $\nabla_{pq} V = (\hat{R}, s)$ is the unit vector in the radial direction $R$. Given the particular position of the local dihedral $p, q$ in the $L^k$-side evaluation, we have $(\hat{R}, s) = -q = -q$ and then

$$(\nabla_{pq} V, s) = -q \left( \frac{\partial V}{\partial R} \right).$$

(10)
and the function $F$ is

$$F = 2|\eta|\tan^{-1}\left[\frac{p - |\eta|}{q}\right] - q \ln(p + r)$$

But, the sum by differences between the vertices of the $L^k$ side of the function $\tan^{-1}(p/q)$ can be written as $\beta_k = \beta_{k+1/2} - \beta_{k-1/2}$, where

$$\beta_{k+1/2} = \tan^{-1}\left[\frac{p_{k+1/2}}{q_{k+1/2}}\right];$$

where $\beta_k$ is the view angle for the $L^k$ side from the $O$ local origin. Its sum over the closed perimeter is null and then this term will be omitted in $F$. We also note that the local origin $O$ is the projection of the observation point $x_0$ on the panel plane and is fixed during the integration. Then, the monopolar influence coefficient $C_{ij}$ between the source panel and the collocation point $x_i$, is the sum of the $M$ contributions

$$C_{ij} = \sum_{k=1}^{M} \beta_k$$

where $p_{k+1/2}$ are its extreme abscissas and $q$ the common ordinate, in the side dihedral $p, q$ with $p$ parallel to the $L^k$ side. The (reduced) auxiliary function $F = F(p, q, n)$ is

$$F = 2|\eta|\tan^{-1}\left[\frac{p - |\eta|}{\sqrt{p^2 + q^2 + \eta^2}}\right] - q \ln(p + \sqrt{p^2 + (q^2 + \eta^2)}).$$

By direct computation we can verify the classical properties of the monopolar potential [1,2], for instance, let us consider the monopolar coefficient $C_{ij}$ as a function of the observation point $p, q, \eta$ over a normal line passing through the panel centroid: (i) is a symmetrical function of the distance $\eta$ between the observation point and the panel surface $C(p, q, \eta) = C(p, q, -\eta)$, and (ii) the tangents to the curve $C(p, q, \eta) = f(\eta)$ at the origin $\eta = 0$ are finites and the opposite sign, so the normal derivative $\partial C/\partial \eta$ has a finite jump to crossing the panel (Fig. 3). In Fig. 4 we show the monopolar intensity $C(p, q, \eta)$ for points $(p, q, \eta)$ over the planes $\alpha$ parallel to the panel for two values of $\eta$.

5. Logarithmic singularity in the monopolar matrix

In the monopolar matrix $C$ a singularity appears when both $\eta$ and $\eta'$ vanish simultaneously, which is common, for instance, in flat-structured surfaces meshes as in ship-wave calculations, since all these panels are coplanar, so $\eta = 0$, and many of them will have side terms with $q = 0$, which can be arrived at by direct computation on a sample mesh, whereas the node coordinates from the projection point $O$ are $p_1, p_2 > 0$ or $p_1, p_2 < 0$ for such flat-structured meshes (Fig. 5). The singularity is due to the logarithm term

$$\Delta b = \ln\left|\frac{b_2}{b_1}\right| = \ln\left|\frac{p_2 + \sqrt{p_1^2 + q^2 + \eta^2}}{p_1 + \sqrt{p_1^2 + q^2 + \eta^2}}\right|.$$ (26)

When $q = \eta = 0$, simultaneously, we have

$$\Delta b = +\ln\left|\frac{p_2 + |p_2|}{p_1 + |p_1|}\right|$$

for $p_1, p_2 > 0$; (27)

which is a regular term. But, when $p_1, p_2 < 0$ we have $\Delta b = NaN$ (undefined). In order to overcome this shortcoming, we employ the classical technique of subtracting the
singularity, i.e.

\[
\Delta b = \ln \left\{ \frac{p_2 + r_2}{p_1 + r_1} - \frac{p_2 - r_2}{p_1 - r_1} \right\},
\]

where \( r_{1,2} = p_{1,2}^2 + q^2 + \eta^2 \) so that

\[
\Delta b = \ln \left\{ \frac{r_2^2 - p_2^2}{r_1^2 - p_1^2} - \frac{r_2^2 + p_2^2}{r_1^2 + p_1^2} \right\}.
\]

but \( r_2^2 - p_2^2 = r_1^2 - p_1^2 = q^2 + \eta^2 \); then

\[
\Delta b = -\ln \left\{ \frac{p_2^2 + q^2 + \eta^2 - p_2}{p_1^2 + q^2 + \eta^2 - p_1} \right\}.
\]

When \( q = \eta = 0 \), simultaneously we have

\[
\Delta b = -\ln \frac{p_2}{p_1} \quad \text{for} \quad p_1, p_2 \leq 0.
\]

Both Eqs. (27) and (31) can be reduced to

\[
\Delta b = \ln \left\{ \frac{p_2 + r_2}{p_1 + r_1} - \frac{p_2 - r_2}{p_1 - r_1} \right\}.
\]

From a computational viewpoint, we suppose that \( q = \eta = 0 \) is present when the condition \( \sqrt{q^2 + \eta^2} < \varepsilon \max \{ |p_1|, |p_2| \} \) is verified, where \( \varepsilon \) is a fixed tolerance.

6. Dipolar matrix

The dipolar matrix \( \tilde{A}_{ij} \) is found from

\[
\tilde{A}_{ij} = \int_{S^i} d\gamma \frac{\partial}{\partial n} \frac{1}{r};
\]

where \( \partial \) is the normal derivative to the surface panel. The dipolar kernel \( \partial_{n_2} r^{-1} \) can be expressed as

\[
\frac{\partial}{\partial n} = \frac{\partial}{\partial r} \frac{r}{r} = -\frac{1}{r} \frac{\partial}{\partial n} = -\frac{\eta}{r^3};
\]

Again we employ the previous strategy: we find an auxiliary function \( W(R, \eta) \) such that its bidimensional Laplacian \( \Delta_{pq} W \) over the panel surface is equal to the dipolar kernel \( -\eta/r^3 \), i.e.

\[
\Delta_{pq} W = -\frac{\eta}{r^3};
\]

Then, the surface integral is replaced by the line integral by means of the 2D-divergence theorem

\[
\tilde{A}_{ij} = \int_{S^i} \Delta_{pq} W \, dS_{pq} = \int_{S^i} (\nabla_{pq} W, s) \, dL;
\]

where \( W(R, \eta) \) is a regular enough function which is found from the solution of the differential equation

\[
\frac{1}{R} \frac{\partial}{\partial R} \left( R \frac{\partial W}{\partial R} \right) = -\frac{\eta}{(R^2 + \eta^2)^{3/2}};
\]

where \( \Delta_{pq} W \) is the bidimensional Laplacian in the \( R, \eta \) polar coordinates, with \( \partial \) \( W = 0 \). The integration gives:

\[
W = \int_{R_0^2 / 2}^{R_0^2 / 2 + \eta^2} \frac{dR}{R};
\]

which admits the solution

\[
\tilde{A}_{ij} = \int_{s^i} (\nabla_{pq} W, s) \, dL;
\]

The \( s \) component of the gradient \( \nabla W \) is

\[
(\nabla_{pq} W, s) = \frac{\partial W}{\partial R} \frac{(R, s)}{R};
\]

due the position of the local dihedral \( p, q \) for the \( L^k \) side we

\[
\tilde{A}^k = \sum_{k=1}^{M} \tilde{A}^k \quad \text{where} \quad \tilde{A}^k = \int_{s^i} (\nabla_{pq} W, s) \, dL;
\]
Fig. 7. Intensity of the dipolar coefficient \( A(p, q, \eta = 0.01) \) over the planes \( \alpha = 0.01 \) (left) and \( \eta = 0.5 \) (right).

The dipolar intensity remains continuous when crossing the panel (Fig. 6). In \( D \) where the auxiliary dipolar function \( D \) is

\[
(\nabla_{\eta} W, s) = q \operatorname{sgn}(\eta) \frac{1}{|R^2 + \eta^2 - |\eta||R^2 + \eta^2|}
\]

\[
- q \operatorname{sgn}(\eta) \frac{1}{R^2}.
\]

The dipolar line integral on the \( L^k \) side, is written as

\[
\Lambda^k = D(p_{k+1/2}, q, \eta) - D(p_{k-1/2}, q, \eta);
\]

where the auxiliary dipolar function \( D(p, q, \eta) \) is the sum

\[
D = q \operatorname{sgn}(\eta) D_1 - q \operatorname{sgn}(\eta) D_2.
\]

The integral \( D_1 \) is the same as the monopolar \( F_1 \). The integral \( D_2 \) is equal to the monopolar term \( F_2 \), so its closed sum around the panel perimeter is null. Then, the dipolar influence coefficient \( \Lambda_{ij} \) between the \( j \)-source panel and the collocation point \( x_i \), is the sum of the \( M \) contributions

\[
\Lambda_{ij} = \sum_{k} \Lambda_{ik} \text{ where }
\]

\[
\Lambda_{ik} = D(p_{k+1/2}, q, \eta) - D(p_{k-1/2}, q, \eta);
\]

where

\[
D = 2 \operatorname{sgn}(\eta) \tan^{-1} \left[ \frac{p - |\eta| - \sqrt{p^2 + q^2 + \eta^2}}{q} \right].
\]

Again, by direct computation we can verify the classical properties of the dipolar coefficient \([1,2]\). For instance, let us consider the monopolar coefficient \( A \) as a function of the observation point \( p, q, \eta \) over a normal line passing trough the panel centroid: (i) a skew-symmetric function of the distance \( \eta \) between the observation point and the panel surface \( \tilde{A}(p, q, \eta) = -\tilde{A}(p, q, -\eta) \), and (ii) the tangents to the curve \( \tilde{A}(p, q, \eta) = f(\eta) \) at the origin \( \eta = 0 \) are finites and with the same sign, so the normal derivative \( \partial_n(A) \) remains continuous when crossing the panel (Fig. 6). In Fig. 7 we show the dipolar intensity \( A \) for points over the planes \( \alpha \) parallel to the panel for two values of \( \eta \).
